Project 3 Report

In project 3 we modified the file **slob.c** to use the best-fit algorithm to allocate a page and a block of memory. We implemented two system calls to compare the degree of fragmentation between first-fit and best-fit algorithms.

Each member contributed to the project. Maurely Acosta tested both the first fit and best fit algorithm, wrote code and fixed errors in `slob_page_alloc()`, `sys_get_slob_amt_claimed`, and `sys_get_slob_amt_free`. She also contributed to writing the report. Tomas Ortega wrote the helper function `slob_check_page`, contributed to the report, and tested both the first fit and best fit algorithms.

First, we implemented both system calls in the existing **slob.c** file to test the first-fit algorithm and followed the instructions in project 2 to do so. To do this we created two global arrays, one for the amount of memory claimed by the slob allocator and the other one for the amount of memory in the list of free pages. We used a flag to check if we are iterating through the `free_slob_small` list. To test the system calls we wrote the program **testProject3.c** which allocates different amounts of memory using the function `malloc()` and then prints the values returned by the system calls.

To implement the best fit algorithm, we first modified the function `slob_alloc()`. We decided that to find the best page we need to keep the amount of memory that would remain in the page if we decide to choose it for the allocation. To find the amount of free memory remaining after the allocation we decided to implement a helper function `slob_check_page()`.

This function works exactly the same as `slob_page_alloc()` but instead of allocating the block, it returns the amount of remaining if we decide to choose that page. So, while we iterate through the list we need to call `slob_check_page()` and compare it to the best page yet and keep the one with the smallest remaining memory.

The first fit algorithm had 695587 bytes free and 174 bytes claimed. We can see that the memory is highly fragmented and when the system tried to claim memory the remaining free bytes are too small to be used. The advantage is that memory allocation will be done fast since we don't need to traverse the entire list.

The best fit algorithm had 212190 bytes free and 138 bytes claimed. There is still fragmentation with this algorithm but it is much less fragmentation than the first fit algorithm. The amounts of free bytes still exceed that amount we are trying to allocate. The advantage of this algorithm is we reduce fragmentation by allocating memory in a size that fits just right. The disadvantage is that we must traverse the entire list in order to find the best fit.

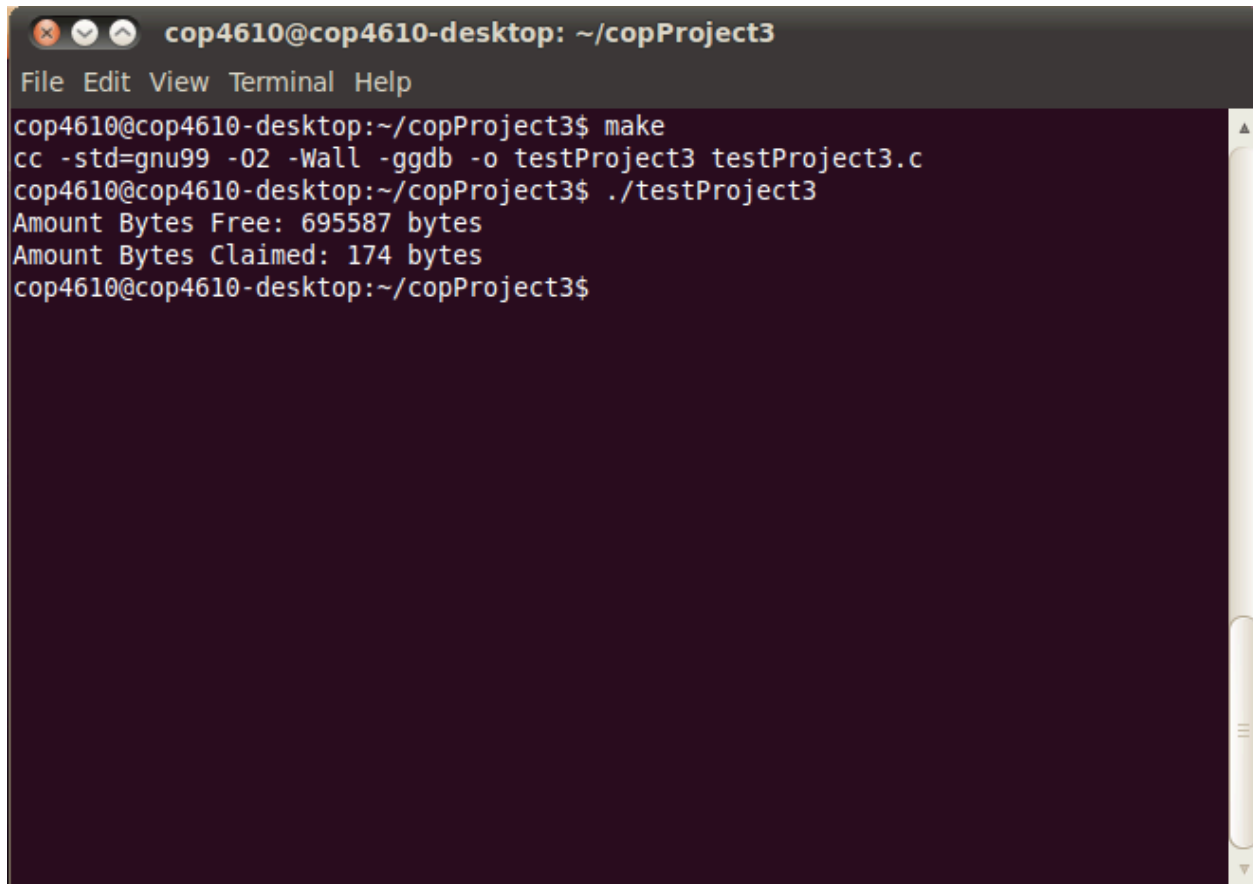

To emphasize, from the values that we got from the system calls we can arrive at the conclusion that the first-fit algorithm is better than best-fit for small memory allocation. The best-fit algorithm ends up leaving tiny spaces of memory that will never be used causing fragmentation. Best-fit is also slower than first-fit since it has to search through the entire list to find the best candidate.
